1 Introduction

This section outlines the scope of the article [EXAMPLE 2024]. The central question motivating this work can be stated as follows: given a dataset $\mathcal{D} = \{(\mathbf{x}_i, y_i)\}_{i=1}^N$, how should one choose a model class $\mathcal{M}$ that balances expressiveness with generalisation? We address this question through both theoretical analysis and empirical evaluation.

2 Methodology

Our approach builds on the framework of regularised empirical risk minimisation. Given a hypothesis $h \in \mathcal{H}$, the objective function is

$$\mathcal{L}(h) = \frac{1}{N} \sum_{i=1}^N \ell(h(\mathbf{x}_i), y_i) + \lambda \Omega(h), \quad [1]$$

where ℓ is a convex loss function and $\Omega(h)$ is a complexity penalty with regularisation strength $\lambda > 0$.

3 Results

We evaluate the proposed method on three benchmark datasets. Table 1 summarises the performance.

Figure 1 illustrates the training convergence behaviour.

Table 1: Classification accuracy (%) on benchmark datasets..

Method	Dataset A	Dataset B	Dataset C	Average
Baseline	82.3	76.1	88.5	82.3
Proposed	89.7	83.4	92.1	88.4

**Figure 1:** Convergence of training and validation loss over 200 epochs..

4 Discussion

The results in Table 1 demonstrate consistent improvements across all three benchmarks [EINSTEIN 1905]. The largest gain is observed on Dataset B, which contains the highest label noise, suggesting that the regularisation term effectively mitigates overfitting.

5 Conclusion

Key findings are highlighted in this section [GOOSSENS et al. 1993]. The proposed method achieves state-of-the-art accuracy while maintaining computational efficiency, making it suitable for deployment in resource-constrained environments.
